ABSTRACT

This tutorial concerns the ranking and selection problem of choosing that one of k normal populations (with common known variance) which has the largest mean. We discuss a number of procedures which guarantee a specified probability of selecting the correct population. We concentrate on so-called indifference-zone procedures.

1. INTRODUCTION

Ranking and selection procedures are a collection of methods which enable an experimenter to answer such statistical questions as:

- Which of k normal populations has the largest mean?
- Which of k Bernoulli populations has the largest "success" probability?
- Which is the most probable cell of a multinomial distribution?

The purpose of this tutorial is to introduce the reader to basic ranking and selection notation and techniques. We concentrate on the problem of choosing that one of k normal populations (with common known variance) which has the largest mean. This problem serves as a springboard to the other questions mentioned previously. For more comprehensive treatments on ranking and selection, see Gibbons, Olkin, and Sobel (1977) and Gupta and Panchapakesan (1979).

The organization of this paper is as follows. In Section 2, we discuss the so-called indifference-zone approach in ranking and selection. Section 3 introduces and compares a number of procedures for finding the normal population with the largest mean. An overview is given in Section 4.

2. THE INDIFFERENCE-ZONE APPROACH

Suppose \( \pi_1, \ldots, \pi_k \) are k normal populations such that \( \pi_i \) has mean \( \mu_i \) and common known variance \( \sigma^2 \), \( i = 1, \ldots, k \). We wish to ascertain which of the k \( \pi_i \)'s has the largest mean; we shall hereinafter refer to that \( \pi_i \) as the "best" population. Let \( \mu_1 ^*, \mu_2 ^*, \ldots, \mu_k ^* \) denote the ordered but unknown \( \mu_i \)'s. We do not know the values of the \( \mu_i ^* \)'s nor do we know how they are paired with the \( \pi_i \)'s. So the goal of finding the best \( \pi_i \) can be restated as that of finding the population corresponding to \( \mu_k ^* \).

A typical procedure for choosing the best population usually requires the experimenter to take a certain number of observations in a prescribed way from each \( \pi_i \); the selection is then made using statistics calculated from these observations. Since the observations are realizations of random variables, it is possible that the experimenter will not choose the best \( \pi_i \). However, if the best population is indeed chosen, we say that the experimenter has made a correct selection (CS).

In order to implement the procedures which will be discussed in this tutorial, the experimenter must supply two constants, \( S^* \) and \( P^* \).
prior to the start of experimentation. \( \delta^* > 0 \) is specified with the following thought in mind: If \( \mu[k] - \mu[k-1] \) is very small, it stands to reason that an experimenter would regard the populations corresponding to \( \mu[k] \) and \( \mu[k-1] \) as practically the same. So \( \delta^* \) is chosen as the smallest value of \( \mu[k] - \mu[k-1] \) that the experimenter views as "worth detecting." In other words, if \( \mu[k] - \mu[k-1] \) were to be \( \geq \delta^* \), the experimenter would prefer to choose the \( \Pi_i \) associated with \( \mu[k] \); if \( \mu[k] - \mu[k-1] \) were to be \( < \delta^* \), the experimenter would be indifferent about choosing either the population corresponding to \( \mu[k] \) or that corresponding to \( \mu[k-1] \). Hence, \( \delta^* = \inf \{\mu[k] - \mu[k-1] \geq \delta^*\} \) is called the preference-zone, and its complement is the indifference-zone.

The procedures we will examine in the next section guarantee the indifference-zone probability requirement introduced by Bechhofer (1954):

\[ P_{CS} \geq P^* \text{ whenever } \mu \in \Delta_{\delta^*}. \]  

(PR)

Of course, we can force \( P_{CS} = 1/k \) simply by choosing as best one of the \( \Pi_i \)'s at random. To avoid this triviality, we require \( 1/k < P^* < 1 \).

3. INDIFFERENCE-ZONE PROCEDURES

In this section, we discuss a number of indifference-zone procedures [i.e., procedures which satisfy (PR)] for finding that one of \( k \) normal populations with common known variance which has the largest mean.

3.1 A Single-Stage Procedure

If the size of the sample to be taken from each \( \Pi_i \) is a constant determined prior to the start of experimentation, we say that the procedure is a single-stage procedure. We first examine a single-stage procedure due to Bechhofer (1954).

Procedure \( P_B \):

1. Specify \( \{k, \sigma^2, \delta^*, P^*\} \), with \( \delta^* > 0 \) and \( 1/k < P^* < 1 \).

2. Calculate \( n_B = \lceil (c_{k, p^*} \sigma/\delta^*)^2 + 1 \rceil \), where \( c_{k, p^*} \) is a tabled constant [see, e.g., Bechhofer (1954)], and \( \lceil \cdot \rceil \) is the greatest integer ("floor") function.

3. Take \( n_B \) independent observations from each of the \( k \) populations.

4. Let \( x_{ij} \) denote the \( j \)th observation from \( \Pi_i \), \( i = 1, \ldots, k \) and \( j = 1, \ldots, n_B \). Calculate the \( k \) sample means:

\[ \bar{X}_i = \frac{1}{n_B} \sum_{j=1}^{n_B} x_{ij}, \quad i = 1, \ldots, k. \]

5. Select as best that population corresponding to the largest \( \bar{X}_i \).

As a simple example, suppose that \( k = 3 \), \( P^* = 0.75 \), and \( \delta^* = 0.2 \). From the tables in Bechhofer (1954), we have \( c_{3, 0.75} = 1.4398 \). Further suppose that \( \sigma^2 = 1 \). Then \( n_B = \lceil 52.39 \rceil = 52 \). So we must take 52 independent observations from each of the three populations.

3.2 An Open Sequential Procedure

If a procedure is not a single-stage procedure, we shall say that it is multi-stage (or sequential). A sequential procedure is open if, prior to the start of sampling, the experimenter can not place an upper bound on the number of observations to be taken from each population. Otherwise, a sequential procedure is closed. The next procedure is an open sequential procedure from Bechhofer, Kiefer, and Sobel (1968).

Procedure \( P_{BKS} \):

1. Specify \( \{k, \sigma^2, \delta^*, P^*\} \), with \( \delta^* > 0 \) and \( 1/k < P^* < 1 \).

2. Set the stage counter \( n \rightarrow 0 \).

3. Set \( n \rightarrow n + 1 \). Take one observation \( x_{in} \) from each \( \Pi_i \), \( i = 1, \ldots, k \).

4. For all \( i \), calculate

\[ y_{in} = \frac{1}{n} \sum_{j=1}^{n} x_{ij}. \]

Further, let \( y_{\max} = \max_{1 \leq i \leq k} y_{in} \).

371
5. Calculate
\[ Z_n = \sum_{i=1}^{k} \exp\{-\delta^*(\gamma_{\text{max}} - \gamma_i)/\sigma^2\} \]

6. If \( Z_n \leq 1/P^* \), stop sampling, and select as best \( \pi_i \) corresponding to \( \gamma_{\text{max}} \). Otherwise, go to Step 3.

Let \( N_{BKS} \) denote the random number of stages required for Procedure \( P_{BKS} \) to terminate (i.e., the value of the stage counter \( n \) at procedure termination). Clearly, the distribution of \( N_{BKS} \) depends on the underlying configuration of the population means \( \bar{\mu}_i, \ldots, \bar{\mu}_k \). Two configurations are of special interest:

If \( \bar{\mu}_k < \bar{\mu}_{k-1} < \ldots < \bar{\mu}_1 - \delta^* \), we say that \( \bar{\mu} \) is in the least favorable configuration (LFC). The LFC is a "worst case" configuration for \( \bar{\mu}_i \)'s in the preference-zone.

If \( \bar{\mu}_k = \bar{\mu}_{k-1} = \ldots = \bar{\mu}_1 - \delta^* \), we say that \( \bar{\mu} \) is in the equal means configuration (EMC). The EMC is a "worst case" configuration over the entire space of \( \bar{\mu} \)'s.

Denote the expected number of stages for Procedure \( P_{BKS} \) when \( \bar{\mu} \) is in the LFC (EMC) by \( E[N_{BKS}|\bar{\mu}|LFC] \) (\( E[N_{BKS}|\bar{\mu}|EMC] \)). It can be shown that the LFC maximizes \( E[N_{BKS}] \) over all configurations in the preference-zone. That is, \( E[N_{BKS}|\bar{\mu}|LFC] \geq E[N_{BKS}|\bar{\mu}|EMC] \). Consideration of the EMC is also important since \( E[N_{BKS}|\bar{\mu}|EMC] \) for all \( \bar{\mu} \). If (unknown to the experimenter) \( \bar{\mu} \) is in the EMC, Procedure \( P_{BKS} \) might be quite costly to run until natural termination.

Continuing our simple example, again suppose that \( k = 3, \sigma^2 = 1, P^* = 0.75 \), and \( \delta^* = 0.2 \). Bechhofer and Goldman (1966) show that, for this example, Procedure \( P_{BKS} \) yields \( P[\bar{\mu}|LFC] = 0.777, E[N_{BKS}|\bar{\mu}|LFC] = 38.00, \) and \( E[N_{BKS}|\bar{\mu}|EMC] = 47.98 \). Thus, for this example, these expected values are smaller than the 52 observations required by the single-stage Procedure \( P_B \). The number of observations required by \( P_B \) is determined before the start of experimentation, and is independent of \( \bar{\mu} \) once sampling commences.

An unappealing feature of \( P_{BKS} \) is the fact that it is open. Bechhofer and Goldman (1966) note that \( P_{BKS} \) always yields \( P[CS|\bar{\mu}|LFC] \) which is larger than the desired \( P^* \). (In the previous example, \( P[CS|\bar{\mu}|LFC] \geq 0.777 > 0.75 = P^* \).) They study a closed version of \( P_{BKS} \) which uses sampling truncation that is, the automatic termination of sampling after a certain predetermined number of stages have been conducted. Compared to \( P_{BKS} \) truncation results in less probability "overprotection", as well as slightly smaller expected numbers of stages.

3.3 A Closed Sequential Elimination Procedure

We next discuss an interesting class of sequential procedures due to Paulson (1964). As sequential sampling proceeds, populations which appear to be inferior are permanently eliminated from further consideration.

Procedure \( P_{C} \):

1. Specify \( k, \sigma^2, \delta^*, P^* \) with \( \delta^* > 0, 1/k < P^* < 1, \) and \( 0 < \lambda < \frac{\delta^*}{\lambda} \). [Paulson suggests taking \( \lambda = \frac{\delta^*}{4}; \) indeed, empirical calculations in Ramberg (1966) show that such a choice often results in considerable savings of observations over other values of \( \lambda \). However, it can be shown analytically that as \( P^* \) approaches 1, the choice \( \lambda = \frac{\delta^*}{\lambda} \) is, in a certain sense, optimal.]

2. Calculate the quantities
\[ a_\lambda = \frac{\sigma^2}{2 \delta^* \lambda} \ln \left( \frac{k-1}{k P^*} \right) \]

and
\[ \lambda_{\lambda} = \frac{\sigma^2}{2 \lambda \ln \left( \frac{k-1}{k P^*} \right)} . \]

3. Initialize the stage counter \( n \leftarrow 0 \) and the set of contending (non-eliminated) populations \( I_0 \leftarrow \{1, 2, \ldots, k\} \).

4. Set \( n \leftarrow n + 1 \). Take one observation \( X_{in} \) from each \( \pi_i \) such that \( i \in I_{n-1} \).

5. For all \( i \in I_{n-1} \) calculate
\[ Y_{in} = \frac{Y_i}{n+1} X_{ij} \]

Further, let \( Y_{\max} = \max_{i \in I_{n-1}} Y_{in} \).

372
6. Determine the new set of containing populations:
\[ I_n = \{ i \in I_{n-1} | y_{i, \text{max}} - y_{i, \text{min}} < n_{\lambda} - n_{\lambda} \} \].

7. If the cardinality \( |I_n| = 1 \) or if \( n = n_{\lambda} + 1 \), then terminate sampling, and select as best that \( \pi_i \) corresponding to \( y_{i, \text{max}} \). Otherwise (\( |I_n| > 1 \) and \( n \leq n_{\lambda} \)), go to Step 4.

Let \( n_p \) denote the random number of stages required for procedure \( P_p \) to terminate sampling. We ran a Monte Carlo experiment for our simple example with \( k = 3 \), \( \sigma = 1 \), \( p^* = 0.75 \), \( \delta = 0.2 \), and \( \lambda = \lambda^* \). The experiment revealed that \( P(CS)^{\gamma_{LFC}^M} = 0.86 \), \( E[n_p | \gamma_{LFC}^M] = 79.06 \), and \( E[n_p | \gamma_{LFC}^M] = 100.57 \). The tremendous probability overshoot \( (P(CS)^{\gamma_{LFC}^M} > p^*) \) is purchased at the expense of the expected values, both of which are much greater than the corresponding values from Procedures \( P_B \) and \( P_{BKS} \). However, as alluded to previously, \( P_p \) performs more parsimoniously (for this example) when \( \lambda = \lambda^*/4 \). Also, it turns out that the performance of \( P_p \) improves when \( p^* \) is closer to unity. Further, improvements in the Paulson procedure due to Fabian (1974) and Hartmann (1985) greatly reduce the expected values to competitive levels.

An advantage of an elimination-type procedure such as \( P_p \) is the fact that once a population is eliminated, no additional observations are ever taken from that \( \pi_i \). Thus, whereas Procedures \( P_B \) and \( P_{BKS} \) require \( kn_B \) and \( kn_{BKS} \) total observations, respectively (i.e., \( k \) observations per stage), Procedure \( P_p \) requires less than \( kn_p \) total observations.

3.4 A Two-Stage Elimination Procedure

It can sometimes be costly (in terms of time and money) to take observations sequentially. Rather, the experimenter might prefer to conduct the entire selection procedure in one or two stages, both of which take a predetermined number of observations from each population. Tamhane and Bechhofer (1977,1978) give a class of two-stage procedures for finding the best population. We will concentrate here on the two-stage procedure which they denote as \( P^*_2(C_2) \); for simplicity, we shall call this Procedure \( P_{TB} \). Procedure \( P_{TB} \) is an elimination procedure since, after the first stage, \( P_{TB} \) eliminates from further consideration populations which seem to be inferior.

Procedure \( P_{TB} \):

1. Specify \( \{ k, \sigma^2, \delta^*, p^* \} \) with \( \delta^* > 0 \) and \( 1/k < p^* < 1 \).

2. Find constants \( c_1, c_2, \) and \( d \), tabulated in Tamhane and Bechhofer (1979), pp. 346-349.

3. Calculate the constants

\[ n_1 = \max(\sqrt{c_1}, \sqrt{c_2} + 1), \]
\[ n_2 = \sqrt{c_2}, \]
\[ h = \delta^*/c_1. \]

\( n_1 \) is the sample size to be taken from each (contending) population in the first (second) stage of experimentation. \( h \) is a constant which will be used in the elimination process.

4. First stage of sampling: Take \( n_1 \) independent observations from each of the \( \pi_i \)’s.

5. Calculate the \( k \) first stage sample means:

\[ \bar{Y}_{i} = \frac{1}{n_i} \sum_{j=1}^{n_i} Y_{ij}, \quad i = 1, \ldots, k. \]

Further, let \( \bar{Y}_{\text{max}}^{(1)} = \max_{1 \leq i \leq k} \bar{Y}_{i}^{(1)}. \)

6. Determine which populations will enter the second stage of sampling:

\[ I = \{ i | \bar{Y}_{i}^{(1)} > \bar{Y}_{\text{max}}^{(1)} - h \}. \]

7. Second stage of sampling: If \( |I| = 1 \), stop sampling and select as best the single contending \( \pi_i \). Otherwise, take \( n_2 \) additional observations from all \( \pi_i \)’s such that \( i \in I \).

8. Calculate

\[ \bar{Y}_i = \frac{1}{n_1 + n_2} \sum_{j=n_1}^{n_1 + n_2} Y_{ij}, \quad i \in I. \]

Further, let \( \bar{Y}_{\text{max}}^{(2)} = \max_{i \in I} \bar{Y}_i. \)
9. Select as best that \( n_1 \) corresponding to \( \max \) \( n \) .

Continuing our example, let \( k = 3 \), \( \sigma^2 = 1 \), \( P^* = 0.75 \), and \( \delta^* = 0.2 \). Referring to the Tamhane and Bechhofer tables, we find that \( c_1 = 0.9989 \), \( c_2 = 0.9495 \), and \( \Delta = 3.089 \). Simple calculations give \( n_1 = 25 \) and \( n_2 = 23 \). So the maximum possible number of observations taken from a given population is 48.

Procedure \( P_{TB} \) possesses a number of appealing properties: Let \( T_{TB} \) denote the (random) total number of observations required by \( P_{TB} \). It can be shown that \( P_{TB} \) is uniformly better than the single-stage Procedure \( P_B \); \( T_{TB} \) is always less than \( knp \). Procedure \( P_{TB} \) is (approximately) minimax in the sense that \( \sup_H E[T_{TB}] \) is (approximately) minimized subject to (PR), \( n_1 \) and \( n_2 \) nonnegative integers, and \( h \geq 0 \).

4. OVERVIEW AND EXTENSIONS

The procedures outlined in Section 3 serve to give the reader the flavor of various simple indifference-zone procedures. Comparison among the above procedures is the subject of current research. We also point out that the LFC and EKC are not the only configurations of interest. In a real-life application, the experimenter might very well be conservative in his choice of \( \delta^* \); that is, he may actually expect \( \mu(k) - \mu(k-1) > \delta^* \). Therefore, another interesting research topic concerns the extent to which such a "favorable" configuration of \( \mu_1 \)'s improves selection procedure performance.

Ranking and selection techniques exist to find the best normal population when less information about the variances is available. For instance, we might only assume that the \( k \) populations have common (but unknown) variance. Or, we might assume that the variances are completely unknown. Generalizing further, we might be interested in selecting that component of a \( k \)-variate normal population which has the largest mean.

As mentioned previously, ranking and selection methods extend beyond normal populations. For instance, it might be desired to select the best of a number of drug treatments in a clinical trial; such a selection amounts to choosing that Bernoulli population with the largest "success" parameter. Perhaps the experimenter is interested in choosing the most popular variety of a certain product; it is possible to interpret this problem as that of determining the most probable multinomial cell.

The indifference-zone approach is not the only methodology available to practitioners. A large class of so-called subset selection procedures [introduced by Gupta (1956)] is available.

Also of interest is the fact that many ranking and selection procedures can directly be extended for use in the computer simulation environment. This is a bit surprising since most ranking and selection procedures require independent and identically distributed observations within each population - a situation which is rarely present in simulations. See Goldman (1983,1985) for relevant surveys.

ACKNOWLEDGMENT

The author thanks Prof. Robert E. Bechhofer for his encouragement.
